INTERCOMPARISON OF THE OFFSHORE WAVE MEASUREMENTS DURING ARSLOE

Michael W. Szabados
Marine Environmental Services Division
NOAA/National Ocean Survey
Rockville, Maryland 20852

ABSTRACT

Preliminary results of an intercomparison between several wave measurement systems used during the ARSLOE experiment are presented. The comparison consists of some of the measurements in the offshore region, 12 km to 40 km offshore, taken during a storm that occurred October 23 to 26, 1980. The results indicate that differences in significant wave heights can be larger than the random variability.

1. Introduction

During the fall of 1980, the Coastal Engineering Research Center of the U.S. Army Corps of Engineers and the Coastal Waves Program (CWP) of the National Ocean Survey, National Oceanic and Atmospheric Administration jointly hosted the Atlantic Remote Sensing Land-Ocean Experiment (ARSLOE). Participation in the experiment was broad with investigators from Government agencies, foreign countries, industry, and academic institutions using various surface, subsurface, and remote sensing wave measurement systems. One of the purposes of the experiment was to test and compare available wave measurement systems.

ARSLOE included a configuration of wave measurement systems that covered a 40 km x 40 km region off the coast of Duck, North Carolina. This intercomparison concentrates on some of the measurements in the offshore region taken during a 4-day period from October 23 to 26, 1980, when a major storm passed through the site area. The storm was of interest since it consisted of a complex frontal system which resulted in opposing seas.

Table 1 summarizes those systems to be discussed. The location of these systems is displayed in Figure 1. The Cloverleaf Directional Buoy measured waves in various locations ranging from 12 to 40 km offshore while tethered to the Research Vessel CAPE HENLOPEN. The locations for the Airborne Radar systems shown in Figure 1 represent the approximate location of the center for the flight paths. Most buoy measurements are either at 12 or 36 km offshore.

There are some difficulties and limitations when comparing different instrumentation in situ. It would be ideal to have the measurement systems identically located so any difference found could be related only to the measurement systems. Since this is not possible, allowance must be made for differences due to natural variability between deployment locations. Similarly, differences should be expected when comparing a buoy that measures at a point location with a radar system which measures over some finite area. There are other differences due to the dynamics of different moorings, varying sample lengths, and varying analysis methods, such as the window used when computing spectra. Therefore, when interpreting the results, it is important to consider these limitations.

ARSLOE ALPHA, a study prior to ARSLOE, was conducted to provide a measurement of the natural site variability. Three Waveriders were deployed in a line parallel to shore at the 12 km site with the 2 outermost ones positioned 1 km apart. All three instruments were calibrated, used identical mooring configurations, and the data were processed and analyzed with the same software routines. This was done in hope that any differences would be limited to natural variability. It was found, based on 57 pairs of observations, that the significant heights measured by the two outermost Waveriders agreed within their 90 percent confidence limits 80 percent of the time. Although this may vary somewhat under different wave conditions, the comparison of two different types of measurement systems would not be expected to agree any better.

2. Method of Analysis

Since each participant was responsible for his/her processing and analysis, the methods described in this section pertain mainly to Waveriders which were analyzed by the CWP. For details on the analysis of other measurement systems, the respective participant should be contacted. Most of the participants are presenting their findings during these ARSLOE

sessions at Oceans 82. The names of those contributing their data for this intercomparison can be found in the acknowledgements.

The Waverider signal was sampled at a 4 Hz rate. The time series were separated into lengths of 4096 data points representing 1024 seconds so that a FAST Fourier Transform (FFT) algorithm could be used. To reduce side lobe leakage in the spectral estimates the Tukey or cosine bell window,

\[ w(nAt) = \frac{1}{2} \left[ 1 - \cos(2\pi n/N) \right] \]

was applied before the Cooley-Tukey FFT method for computing the complex Fourier series

\[ A_j = a j = \sum_{n=0}^{N-1} A_k \exp(2\pi i jk/N) \]

was used. The spectral estimates were then corrected for variance loss due to the window by applying a ratio of the variance of the spectra and the variance of the original time series before the window. Calibration corrections, which are frequency-dependent, were applied after the variance correction. The applied corrections did not include temperature effects on Waverider sensitivity. This introduced an amplitude error of about 1 percent for the temperatures observed during the storm [1].

The spectral estimates were band-averaged over 11 frequencies resulting in spectral estimates with frequency resolution of 0.011 Hz and 22 degrees of freedom. Variability of the spectral peak is dependent upon frequency resolution and degrees of freedom.

Assuming a narrow band spectrum, the significant wave height was calculated by,

\[ H_s = 4 \sqrt{\frac{m}{2}} \]

where \( m \) = area under the wave spectrum [2].

The 95 percent confidence limits for the true significant wave height, \( H'_s \), were found by:

\[ \left( \frac{Z'}{Z/\sqrt{20} - a} \right)^{1/2} H_s \leq H'_s \leq H_s \left( \frac{Z'}{Z/\sqrt{20} + a} \right)^{1/2} \]

where \( H_s \) is estimated significant wave height, \( Z' \) values are obtained from a chi-square distribution, and \( Z \) the total degrees of freedom is given by:

\[ Z = \sum_{n=1}^{N} \frac{E_n^2}{n} \]

where \( E_n \) is wave variance at the nth Fourier frequency and the summations are over all Fourier frequencies.

The comparison of wave direction pertain only to mean wave direction. The mean wave direction \( \bar{\theta} (f) \) for each frequency band can be computed for the directional wave buoy systems from

\[ \bar{\theta} (f) = \tan^{-1} \left[ \frac{b_1(f) + a_1(f)}{a_1(f) - b_1(f)} \right] \]

where \( a_j \) and \( b_j \) are the Fourier coefficients from the weighted Fourier expansion

\[ F(f, \theta) = \frac{1}{2} a_0 + c_1 (a_1 \cos(\theta) + b_1 \sin(\theta)) + c_2 (a_2 \cos(2\theta) + b_2 \sin(2\theta)) \]

of Longuet-Higgins et al. [3].

3. Results

Figure 2 displays the time history of the suite of wave parameters: significant wave height, frequency of the spectral peak, and mean wave direction of the spectral peak. When interpreting these plots, one must be careful to compare only those stations at the same site. In Figure 2, the notation "1" located above the symbol for the Cloverleaf data represents those data recorded within 1 km of the 12 km site. The "2" above the symbol represents those data recorded within 3 km of the 36 km site. All other Cloverleaf data were taken between these locations.

3.1 Significant Wave Height

Significant wave heights from the measurement systems are plotted in Figure 2a. As shown in this figure and summarized in Table 2, the significant wave heights measured by the Waverider and ENDECO buoys had better agreement before passage of the front, mid-day (GMT) on October 25. Then ENDECO and Waverider agreed within the Waverider 90 percent confidence limits, 85 percent of the time. After the passage of the front, this decreased to 33 percent.

The nondirectional spectra were compared in hope of resolving this difference in significant wave height. It was not possible to differentiate the source of these differences between the ENDECO and Waverider. However, the analysis did distinguish some basic characteristics between the spectra. The examples in Figure 3 represent the spectra normalized by the total spectral density. For this comparison, the spectral estimates for the Waverider were averaged by a moving window over 50 frequency bands to have the same resolution as the ENDECO. It was found that spectral peaks for the ENDECO data were generally broader at the lower frequencies than those for the Waverider. A possible cause for this could have been the different type of window applied. It was also found that the high frequency end of the Waverider spectra did not trail off as quickly as for the ENDECO spectra. A possible reason for this may be the differences in buoy response which were not adequately removed by calibration corrections.

The comparison between the Canadian "MET" buoy and the Waverider is limited to two measurement periods early on October 23. Although these data are insufficient to draw conclusions, Table

* Only those measurements taken before frontal passage on October 25, 1980.
** Only those measurements taken after frontal passage on October 25, 1980.
*** For all measurements.

The significant wave heights measured by the Cloverleaf buoy were found to be consistently higher than those measured by nearby systems. When compared with the values measured at the 12 km site by the Waverider, the Cloverleaf data averaged 15 percent higher. There was one measurement at 1715 (GMT) on October 26, when the Cloverleaf measurement was within the Waverider 90 percent confidence limits. The Cloverleaf buoy measurements taken near the 36 km site averaged 20 percent higher than those taken by the XERB buoy.

The Surface Contouring Radar (SCR) was flown over the experiment area at 2220 (GMT) on October 23. The Waverider which had been deployed at the center of the SCR pattern located 20 km offshore malfunctioned and thereby limited the ground truth data to those data measured at the 12 km and 36 km sites. The significant wave height of 1.55 m measured by SCR had better agreement with that measured by XERB (1.58 m) at 36 km offshore than the Waverider (1.73 m) at 12 km offshore. This might be expected since the bottom slope was greater between the 12 km and 20 km site than between the 20 km and 36 km site.

3.2 Frequency of Spectral Peak

The frequencies of the center of the frequency bands in which spectral peaks occurred for the wave measurements systems are plotted in Figure 2b. After the front passed through the site on October 25, opposing waves developed. The dual spectral peaks of sea and swell, as shown in Figure 3c, were at times about equal which resulted in a random choice of which peak was recognized as the principal peak causing the bifurcation shown in Figure 2b. Table 3 summarizes the results of the spectral peak comparison for single peak spectra. As shown in Figure 2b, the Waverider measured the spectral peak at a lower frequency when compared with the ENDECO. Although this difference is a consistent shift in the spectra, 83 percent of the time it was within the ENDECO frequency resolution of ±0.025 Hz for the single peak spectra.

Although there were only two spectra available for comparison, the "MET" and Waverider measured the same frequency for the spectral peaks. These cases included single peak sea and swell spectra.

The frequency of the spectral peak for the Cloverleaf spectra was found generally in agreement with those spectra from buoys nearby. When compared with the Waverider during both swell or sea, spectra agreed within their frequency resolution 71 percent of the time. When compared with XERB spectra, the measurements agreed 80 percent of the time within the frequency resolution. When comparing the frequency of waves measured by a buoy with

3.3 Mean Wave Direction of the Spectral Peak

The mean wave direction for the frequency of the spectral peak are summarized in Figure 2c for those systems measuring wave direction. Wave directions are referenced to True North and indicate the direction toward which waves propagate.

As shown in Table 4, when the Cloverleaf buoy was near the ENDECO buoy, mean wave directions agreed within 4° to 20°. The wave direction measured by the Cloverleaf buoy indicated a slightly more northerly wave direction than the ENDECO buoy. The Cloverleaf buoy, when in the vicinity of the XERB buoy, showed similar agreement with the difference in mean wave direction ranging between 1° to 24°. The Cloverleaf buoy indicated a more southerly direction of the waves than XERB.

Data from the SLAR overflight near the 12 km site on October 25 did not coincide with the available ENDECO data. The nearest measurements were about an hour apart. These measurements, as shown in Figure 2c, indicate the direction for the ENDECO buoy may be more northerly than that measured by SLAR.

Surface Contouring Radar measurements taken in the region 20 km offshore on October 23 agreed with those measured at the 12 km site by the Cloverleaf buoy. The SCR measured the wave direction to be 210°, while the Cloverleaf measured the direction to be 212°. At the same time, the XERB at 36 km offshore measured the wave direction at 226°.

When the Canadian "MET" buoy recorded measurements on October 23, there was no other wave direction data available for the 12 km site. The only other system measuring wave direction at this time was XERB, some 24 km further offshore. The "MET" data during this time showed the wave direction to be some 30° more northerly.
